A Quantum Leap Into the Future of Chemistry

# Simulating X-ray Absorption and Emission Spectra with TDDFT

**X-ray absorption (XAS) and emission (XES) spectroscopy**

- Difficulty: core-excited states are too high in energy to access through standard bottom-up algorithms for computing excited states.

- Solution: set up a reduced excitation space that includes only relevant core orbitals in the occupied space (as in the core-valence separation scheme).

- Valence-to-core XES transitions are obtained through a TDDFT calculation with a non-Aufbau reference state containing a core hole.

Advantages of using TDDFT for simulating X-ray spectroscopy:

- Good balance between computational accuracy and cost. Can be applied to realistic molecular systems;

- With special-purpose xc functionals (e.g., SRC functionals in Q-Chem), errors in core excitation energies are significantly reduced;

- Only minimal input parameters are necessary (almost).
(a) Simulated XAS for butadiene

(b) Simulated XES for acetone
